(Received 14 March 2011; revised manuscript received 2 June 2011; published 20 July 2011)

The Nernst coefficient of the cuprate superconductor $\text{YBa}_2\text{Cu}_3\text{O}_y$ was recently shown to become strongly anisotropic within the basal plane when cooled below the pseudogap temperature $T^*$, revealing that the pseudogap phase breaks the fourfold rotational symmetry of the CuO$_2$ planes. Here we report on the evolution of this Nernst anisotropy at low temperature, once superconductivity is suppressed by a magnetic field. We find that the anisotropy drops rapidly below 80 K, to vanish in the $T = 0$ limit. We show that this loss of anisotropy is due to the emergence of a small high-mobility electronlike pocket in the Fermi surface at low temperature, a reconstruction attributed to a low-temperature state that breaks the translational symmetry of the CuO$_2$ planes. We discuss the sequence of broken symmetries—first rotational, then translational—in terms of an electronic nematic-to-smectic transition such as could arise when unidirectional spin or charge modulations order. We compare $\text{YBa}_2\text{Cu}_3\text{O}_y$ with iron-pnictide superconductors where the process of (unidirectional) antiferromagnetic ordering gives rises to the same sequence of broken symmetries.

I. INTRODUCTION

Establishing and understanding the normal-state phase diagram of cuprates is of primary importance in the quest to uncover the mechanism of high-temperature superconductivity. The discovery of quantum oscillations in underdoped $\text{YBa}_2\text{Cu}_3\text{O}_y$ (YBCO) revealed that in the absence of superconductivity, suppressed by the application of a large magnetic field, the ground state in the underdoped region of the phase diagram is a metal whose Fermi surface contains a small closed pocket. The negative Hall and Seebeck coefficients of YBCO at $T \rightarrow 0$ show this pocket to be electronlike. The presence of an electron pocket in the Fermi surface of a hole-doped cuprate is the typical signature of a Fermi-surface reconstruction caused by the onset of a new periodicity which breaks the translational symmetry of the crystal lattice.

In the doping phase diagram of YBCO (Fig. 1), the electron pocket exists at $T \rightarrow 0$ (in the absence of superconductivity) throughout the range from $p = 0.083$ to at least $p = 0.152$. We infer that translational symmetry is broken at $T = 0$ over at least that range, by an ordered phase that has yet to be definitively identified. The fact that the Seebeck coefficient of the cuprate $\text{La}_{1-y}\text{Sr}_y\text{Eu}_{0.2}\text{CuO}_4$ (Eu-LSCO) at $T \rightarrow 0$ is negative over the same range of doping as in YBCO, and that stripe order—a unidirectional modulation of spin and/or charge densities—prevails in Eu-LSCO over that doping range, is compelling evidence that stripe order is responsible for the broken translational symmetry and that Fermi-surface reconstruction is a generic property of hole-doped cuprates.

At temperatures above the superconducting transition temperature $T_c$, the normal-state phase diagram of cuprates is characterized by the pseudogap phase, below a crossover temperature $T^*$. The Nernst effect was recently found to be a sensitive probe of the pseudogap phase, such that it can be used to detect $T^*$, as shown in Fig. 1 for YBCO. Measurements of the Nernst coefficient $\nu (T)$ in detwinned crystals of YBCO for a temperature gradient along the $a$-axis and $b$-axis directions within the basal plane of the orthorhombic crystal structure revealed a strong in-plane anisotropy, setting in at $T^*$. This strongly suggests that the pseudogap phase breaks the fourfold rotational symmetry of the CuO$_2$ planes, throughout the doping range investigated, from $p = 0.08$ to $p = 0.18$.

In this paper, we investigate the impact of Fermi-surface reconstruction on this Nernst anisotropy, by extending the previous Nernst study (of Ref. 7) to low temperature. We find that below 80 K the anisotropy falls rapidly, in close parallel with the fall in the Hall coefficient to negative values. We infer that the Nernst anisotropy disappears because the small closed high-mobility electron pocket, which dominates the transport properties of YBCO at low temperature, yields isotropic transport.

II. METHODS

Measurements were performed on high-quality detwinned YBCO crystals grown in a nonreactive BaZrO$_3$ crucible from high-purity starting materials. The oxygen content was set at $y = 6.67$ and the dopant oxygen atoms were made to order into an ortho-VII superstructure, yielding a superconducting transition temperature $T_c = 66.0$ K. The hole concentration (doping) $p = 0.12$ was determined from a relationship between $T_c$ and the $c$-axis lattice constant. The Nernst effect, being the transverse voltage $V$ generated by a longitudinal temperature difference $\Delta T$ in a perpendicular applied magnetic field $H$, was measured in Sherbrooke up to 15 T and at the LNCMI in Grenoble up to 28 T.
cases, we used a one-heater two-thermometer setup and the field was applied along the $c$ axis of the orthorhombic crystal structure. The Nernst signal was measured with the thermal gradient $\Delta T$ either along the $a$ axis ($\Delta T_a$) or the $b$ axis ($\Delta T_b$), and the Nernst coefficient $\nu$ is indexed as follows:

$$\nu_a = \frac{\alpha}{H} \frac{V_b}{\Delta T_a} \quad \text{and} \quad \nu_b = \frac{\alpha}{H} \frac{V_a}{\Delta T_b},$$

(1)

where $\alpha = t/w$ is the ratio of sample length (between thermometer contacts) to sample width.

III. RESULTS

Before we present our results, it is important to emphasize that there are two different contributions to the Nernst effect in a superconductor: (1) a positive contribution from superconductivity (moving vortices and fluctuations of the superconducting order parameter) and (2) a contribution from normal-state quasiparticles, which can be either positive or negative. In YBCO, the two contributions can be readily separated because the quasiparticle contribution is negative, of opposite sign to the signal from superconducting fluctuations.\(^7\)

Note also that the quasiparticle contribution to the Nernst coefficient $\nu(H)$ is mostly independent of field, whereas the superconducting contribution is strongly dependent on field.\(^17\)

In the electron-doped cuprate $\text{Pr}_2-x\text{Ce}_x\text{CuO}_4$, for example, this difference in the field dependence was used to separate the two contributions, both positive in this case.\(^19\)

The amplitude of the quasiparticle contribution may be estimated from the following expression:\(^18\)

$$\left| \frac{\nu}{T} \right| \approx \frac{\pi^2 k_B}{3 e} \frac{\mu}{T_F},$$

(2)

where $k_B$ is Boltzmann’s constant, $e$ is the electron charge, $\mu$ is the carrier mobility, and $T_F$ is the Fermi temperature. This relation, applicable in the $T \to 0$ limit, was found valid within a factor of 2 or so for a wide range of metals.\(^18\) Its implication is that the Nernst effect is highly sensitive to Fermi-surface reconstructions that produce pockets with a small Fermi energy ($\epsilon_F \equiv k_B T_F$) and a high mobility. A good example of this is the heavy-fermion metal $\text{URu}_2\text{Si}_2$ where, upon cooling below $17 \text{ K}$, $\epsilon_F$ drops by a factor of 10 simultaneously with a tenfold rise in the mobility $\mu$. As a consequence, $\nu/T$ rises by two orders of magnitude.\(^20\)

In Figs. 2 and 3, the Nernst coefficient $\nu$ of YBCO at $p = 0.12$ is plotted as $\nu/T$ vs $H$ and vs $T$, respectively, for both $a$- and $b$-axis directions. The high-field $b$-axis data are presented here, while the low-field data\(^7\) and the high-field

FIG. 1. (Color online) Phase diagram of YBCO, showing the zero-field superconducting transition temperature $T_c$ (solid line; Ref. 6, extrapolated as dotted line above $p = 0.18$) and the pseudogap crossover temperature $T^*$ detected by the Nernst effect (squares; Ref. 7). The onset of in-plane anisotropy in the Nernst coefficient below $T^*$ points to a state with broken rotational symmetry (BRS) (Ref. 7). Once superconductivity is suppressed by a magnetic field, the normal state at $T \to 0$ is characterized by a reconstructed Fermi surface (Refs. 1 and 2), evidence of broken translational symmetry (BTS). The temperature $T_H$ below which the Hall coefficient $R_H(T)$ starts to deviate downward is the first signature of Fermi-surface reconstruction upon cooling (open circles; from Ref. 8). The white down-pointing arrow locates the present study of Nernst anisotropy on the phase diagram. The two dashed lines are a guide to the eye.

FIG. 2. (Color online) Nernst coefficient $\nu$ of YBCO at a hole concentration (doping) $p = 0.12$, plotted as $\nu/T$ versus magnetic field $H$, for different temperatures, as indicated. Top: The temperature gradient $\Delta T$ is applied along the $a$ axis of the orthorhombic crystal structure. Bottom: $\Delta T$ is along the $b$ axis. Inset: zoom on the data at high field. The saturation in $\nu$ vs $H$ above $H \simeq 26 \text{ T}$ indicates that the positive contribution from superconducting fluctuations has become negligible, and the data above $26 \text{ T}$ represent the normal-state properties of YBCO at that doping.
a-axis data were reported previously. We start by examining the isotherms. At $T < T_c = 66$ K, $\nu(H)$ shows the strong field dependence typical of a superconductor: (1) at low field, $\nu = 0$ in the vortex solid phase; (2) at intermediate fields, $\nu$ rises to give a strong positive peak; and (3) at higher field, the positive signal gradually decreases, until such fields as $\nu(H)$ becomes flat, where the superconducting contribution has become negligible. At the highest field measured in our experiment (28 T), this saturation has been reached for all temperatures down to $\sim 10$ K, so that we may regard the state at 28 T (and above) as the normal state.

At $T = 85$ K, $\nu_b(H)$ is seen to be totally flat and $\nu_b(H)$ increases very slowly (a form of normal-state magnetoresistance). The positive (field-decreasing) superconducting contribution has become vanishingly small. This shows that in a clean underdoped cuprate the regime of significant superconducting fluctuations does not extend in temperature very far beyond $T_c$. More quantitatively, the superconducting contribution to the Nernst coefficient $\nu/T$ in YBCO at $p = 0.12$ drops to 0.1% of its peak value at $T_c$ by $T \approx 1.35T_c$.

In Fig. 3, we see that the normal-state $\nu/T$ at 28 T is independent of temperatures below $\sim 25$ K. Its large negative value at $T \to 0$ is completely and unambiguously due to quasiparticles. In Fig. 4, we compare the normal-state $\nu_a$ and $\nu_b$ as a function of temperature. We see that the large anisotropy characteristic of the pseudogap phase disappears below $\sim 25$ K.

The in-plane anisotropy of the normal-state $\nu(T)$ is plotted in Fig. 5, as the difference $\nu_a/T - \nu_b/T$ (top panel) and the normalized difference $(\nu_a - \nu_b)/(\nu_a + \nu_b)$ (bottom panel). The Nernst anisotropy is seen to rise just below the pseudogap temperature $T^*$, defined as the temperature below which the $a$-axis resistivity drops below its linear dependence at high temperature. Upon cooling, it continues to rise, until it reaches a maximal value of $(\nu_a - \nu_b)/(\nu_a + \nu_b) \simeq 0.75$ (i.e., $\nu_a/\nu_b \simeq 7$) at $\sim 80$ K. Upon further cooling, however, we now find that the anisotropy drops rapidly, with $(\nu_a - \nu_b)/(\nu_a + \nu_b) \to 0$ (i.e., $\nu_a/\nu_b \to 1$) as $T \to 0$.

IV. DISCUSSION

To elucidate the cause of this dramatic drop in the Nernst anisotropy, we turn to the Hall coefficient $R_H(T)$. In Fig. 5, the normal-state Hall angle $\theta_H$ is plotted as tan $\theta_H = \rho_{xy}/\rho_{xx}$, the ratio of Hall to longitudinal resistivities. Upon cooling, we see that the drop in tan $\theta_H(T)$ to negative values tracks precisely the drop in Nernst anisotropy. (Note that from the Onsager relation, $\sigma_{xy} = -\sigma_{xx}$, $R_H$ is independent of current direction in the basal plane.)

A. Fermi-surface reconstruction

1. Electron pocket

Soon after the discovery of quantum oscillations in YBCO, the fact that the oscillations were seen on top of a large
oscillations, on the other hand, both obtained in YBCO at the same doping, namely, \( p = 0.11 \). Therefore, in the doping interval from \( p = 0.083 \) to at least \( p = 0.152 \), the Fermi surface of YBCO in its nonsuperconducting ground state contains a small closed electron pocket. This pocket dominates the transport properties at low temperature, as discussed in detail in Ref. 8. In particular, it produces a large (quasiparticle) Nernst signal. Applying Eq. (1) to YBCO at \( p = 0.11 \), where quantum oscillations give \( T_H = 410 \pm 20 \) K and \( \mu = 0.02 \pm 0.006 \) T\(^{-1}\),\(^{22}\) yields \( v/T \approx 13 \pm 3 \frac{nV}{K^2 \text{T}} \), while the measured value at \( p = 0.11 \) is \( v/T \approx -13 \pm 3 \frac{nV}{K^2 \text{T}} \),\(^{9}\) in perfect agreement. The somewhat smaller value at \( p = 0.12 \), namely, \( v/T \approx -7 \frac{nV}{K^2 \text{T}} \) as \( T \to 0 \) (Fig. 4), is probably due to the lower mobility expected of samples in the ortho-VIII phase (with \( y = 6.67 \)) compared to those in the ortho-II phase (with \( y = 6.54 \)), consistent with the much weaker quantum oscillations in the former.

The fact that \( v_a \approx v_b \) as \( T \to 0 \) shows that the electron pocket yields transport properties that are isotropic in the plane. This explains the jump in the in-plane anisotropy of the resistivity as the doping drops below \( p = 0.08 \).\(^{23,24}\) Indeed, it was recently discovered that the electron pocket disappears suddenly as the doping is reduced below a critical value \( p = 0.08 \),\(^{8}\) in the sense that for \( p < 0.08 \) both Hall\(^{9}\) coefficients depend weakly on temperature and remain positive at \( T \to 0 \). This change in Fermi-surface topology (or Lifshitz transition) coincides with a tenfold increase in resistivity at \( T \to 0 \),\(^{8}\) showing that the high-conductivity part of the Fermi surface has disappeared. Once the high-mobility electron pocket is removed, the in-plane anisotropy ratio \( \rho_a/\rho_b \) rises (see Ref. 8).

2. Stripe order

The natural explanation for the emergence of an electron pocket in a hole-doped cuprate is the onset of a new periodicity that breaks the translational symmetry of the lattice and thus reduces the Brillouin zone, causing a reconstruction of the large hole Fermi surface into smaller pieces.\(^{4,2} \) A recent study that compares YBCO to the hole-doped cuprate Eu-LSCO found that the Seebeck coefficient behaves in an essentially identical fashion in the two materials, as a function of both temperature and doping.\(^{9}\) \( S/T \) drops to negative values (of very similar magnitude) below the same peak temperature, the sign-change temperature \( T^{*} \),\(^{9}\) is maximal at \( p = 1/8 \) in both cases, and the drop in \( S/T \) disappears below the same critical doping \( p = 0.08 \). So a similar Fermi-surface reconstruction must be taking place in Eu-LSCO as in YBCO, pointing to a generic mechanism of hole-doped cuprates.\(^{9}\)

Now in Eu-LSCO, charge modulations are observed by x-ray diffraction at low temperature,\(^{1,5}\) over the entire doping range where \( S/T < 0 \). Spin modulations are most likely also present, as observed in the closely related material \( \text{La}_{1.6-x}\text{Sr}_x\text{Nd}_{0.4}\text{Cu}_4 \) (Nd-LSCO).\(^{25}\) Called “stripe order,” these spin and charge modulations break the translational symmetry of the CuO\(_2\) planes, and so will cause a reconstruction of the Fermi surface. Calculations for stripe order at \( p = 1/8 \) show that an electron pocket will generically appear,\(^{26}\) causing the quasiparticle Nernst signal to be strongly enhanced,\(^{27}\) as indeed observed in Eu-LSCO (Refs. 14 and 28).

![Figure 5](image-url)

FIG. 5. (Color online) Temperature dependence of the in-plane anisotropy in the normal-state Nernst coefficient of YBCO at \( p = 0.12 \). Top: Nernst anisotropy difference \((v_a - v_b)/T\) vs \( T \) (blue circles, left axis; from Ref. 7). The difference starts to rise below the pseudogap temperature \( T^{*} \) (vertical dashed line). Also shown is the Hall coefficient \( R_H \), measured in a field \( H = 14.5 \) T (continuous red curve, right axis). Below \( \approx 100 \) K, \( R_H(T) \) drops precipitously to reach large negative values at \( T \to 0 \).\(^{2,8}\) We can define the onset of this drop as \( T_H \), the temperature below which \( R_H(T) \) acquires downward curvature (see Fig. 1 and Ref. 8). Bottom: Normalized Nernst anisotropy defined as the dimensionless ratio \((v_a - v_b)/(v_a + v_b)\), plotted vs \( T \) below 120 K (full blue symbols; squares, \( H = 28 \) T, this work; circles, \( H = 14 \) T, from Ref. 7). [Because both \( v_a(T) \) and \( v_b(T) \) cross zero around 150 K, the ratio becomes ill defined above 120 K. To avoid this, we define the sum and difference relative to their value at \( T^{*} \) and plot their ratio above 120 K (open blue circles); see Ref. 7.] Below \( \approx 80 \) K, the anisotropy ratio drops rapidly to zero as \( T \to 0 \) in a way that precisely tracks the drop in the Hall coefficient, shown here as \( \tan \theta_H(T) \equiv \rho_x/\rho_a \) vs \( T \) (continuous red curve, right axis), where the transverse \( \rho_{xx} \) and longitudinal \( \rho_{xx} \) resistivities are measured in 30 T from Ref. 3. This reveals that the disappearance of the Fermi anisotropy at low temperature is due to the Fermi-surface reconstruction that leads to the formation of a small closed electron pocket of high mobility (see text).
and Nd-LSCO. It is then reasonable to infer that stripe order causes the Fermi-surface reconstruction in these underdoped cuprates.

Because stripe order involves unidirectional spin and/or charge modulations, it also breaks the fourfold rotational symmetry of the CuO$_2$ planes. So the reconstructed Fermi surface is expected to have strong in-plane anisotropy, manifested in the calculations by the presence of quasi-one-dimensional open sheets. However, if the conductivity of the relatively isotropic electron pockets is much higher, at low temperature, than that of these open sheets, the inherent anisotropy of the latter will only show up in transport when the electron pocket disappears, as it does below $p = 0.08$.

**B. The pseudogap phase**

We have focused so far on the nonsuperconducting ground state at $T \to 0$, with its stripe order and reconstructed Fermi surface. Let us now ask what happens when the temperature is raised.

The presence of the electron pocket persists at least as long as the Hall coefficient is negative. In YBCO at $p = 0.12$, $R_H(T)$ changes from negative to positive at the sign-change temperature $T_H^b = 70$ K, above $T_c = 66$ K. Of course, the drop in $R_H(T)$ starts at a higher temperature, namely, at the peak in $R_H(T)$ near 90 K (see Fig. 5). In fact, the onset of the downturn is really at the temperature $T_{H}$, where the curvature changes from upward at high temperature to downward at low temperature, i.e., the inflexion point. At $p = 0.12$, $T_{H} \simeq 120$ K (see Fig. 5). In Fig. 1, this temperature $T_{H}$ is plotted vs $p$ on the phase diagram of YBCO. We see that it lies inside the pseudogap phase, between the crossover temperature $T^*$ and the zero-field superconducting temperature $T_c$. This means that the electron pocket starts emerging at temperatures well above the onset of superconductivity, and it does so even in small magnetic fields. In this sense, the onset of Fermi-surface reconstruction is not field induced; it is a property of the zero-field pseudogap phase.

The field serves to suppress superconductivity and allow transport measurements to track the evolution of the Fermi surface to lower temperature. $R_H(T)$ and $S(T)$ become negative below 70 K and 50 K, respectively, and quantum oscillations are detected below 10 K or so. Note that the electrical resistivity $\rho(T)$ has the Fermi-liquid form $\rho_0 + AT^2$ from roughly $T_H$ down to $T \to 0$ (Ref. 8).

If $T_H$ marks the onset of Fermi-surface reconstruction in YBCO as detected in the Hall effect, what corresponding characteristic temperature do we obtain from other transport properties? From the Seebeck coefficient $S/T$ vs $T$, a similar characteristic temperature is obtained, with $T_S \simeq 100$ K at $p = 0.12$. However, the Nernst coefficient, plotted as $v/T$ vs $T$, starts its drop to large negative values at a temperature $T_N$ which is significantly higher, namely, $T_N \simeq 225$ K at $p = 0.12$. (This is independent of direction, the same whether it is measured in $v_u$ or $v_b$.) Calculations show that the quasiparticle Nernst effect is an extremely sensitive probe of Fermi-surface distortions such as would arise from broken rotational symmetry. The value of $T_N$ is plotted as a function of doping in the phase diagram of Fig. 1. We see that $T_N \simeq 2T_H$.

Now $T_N$ coincides with the temperature $T_{\rho}$ below which the in-plane ($a$-axis) resistivity $\rho_{a}(T)$ of YBCO deviates from its linear temperature dependence at high temperature. This $T_{\rho}$ is regarded as the standard definition of the pseudogap crossover temperature $T^*$. The fact that $T_c = T_{\rho}$ at all dopings shows that the drop in $v/T$ to negative values is a property of the pseudogap phase.

Given that the large value of $v/T$ at $T \to 0$ is firmly associated with the small high-mobility electron pocket in YBCO, can $T_c$ therefore be regarded as the onset of Fermi-surface reconstruction as detected in the Nernst effect? By the same token, can $T_H$ be regarded as the onset of incipient Fermi-surface reconstruction detected in the resistivity? If so, then the pseudogap phase would be the high-temperature precursor of the stripe-ordered phase present at low temperature.

Evidence in support of a stripe-precursor scenario is the fact that the enhancement of the Nernst coefficient $v/T$ below $T^*$ is anisotropic, as it would be if the rotational symmetry of the CuO$_2$ planes is broken. This, of course, is a characteristic signature of stripe ordering. Indeed, the sequence of broken symmetries, first rotational then translational, is expected in the gradual process of stripe ordering. The sequence is called “nematic to smectic” ordering. The fact that $T_H$ and $T_0$ are higher than $T_N$ and $T_{\rho}$, by roughly a factor of 2, may come from the role of scattering in the various transport coefficients. Indeed, while $v$ and $\rho$ both depend directly on the scattering rate (or mobility $\mu$), with $v \propto \mu$ and $\rho \propto 1/\mu$, $S$ and $R_H$ do not (at least in a single band model). In other words, if stripe fluctuations affect the transport primarily through the scattering rate, then we would expect $\rho$ and $v$ to be sensitive to the onset of stripe fluctuations, but not $S$ and $R_H$. As we shall now see, similar precursor effects are observed in the iron-pnictide superconductors.

**C. Comparison with pnictide superconductors**

It is instructive to compare the cuprate superconductor YBCO with the iron-pnictide superconductor Ba(Fe$_{1-x}$Co$_x$)$_2$As$_2$ (Co-Ba122). In the parent compound BaFe$_2$As$_2$, a well-defined antiferromagnetic order sets in below a critical temperature $T_N = 140$ K. This order is unidirectional, with chains of ferromagnetically aligned spins along the $b$ axis of the orthorhombic crystal structure alternating antiferromagnetically in the perpendicular direction ($a$ axis). In other words, this is a form of “spin-stripe” order, which breaks both the translational and rotational symmetry of the original tetragonal lattice (present well above $T_N$). As Co is introduced, $T_N$ falls, and superconductivity appears, with $T_c$ peaking at the point where it crosses $T_N$. In other words, in the underdoped region the normal state is characterized by spin-stripe order for some range of temperature above $T_c$. This order causes a reconstruction of the Fermi surface, which leads to a change in the in-plane resistivity: a drop below $T_N$ at low Co concentration $x$, and an upturn at intermediate $x$. However, the upturn starts well above $T_N$. One can define a temperature $T_{\rho}$ below which the roughly linear $T$ dependence at high temperature turns upward. For $3\% < x < 5\%$, $T_{\rho} \simeq 2T_N$. Moreover, the rise in $\rho$ is anisotropic: a strong in-plane anisotropy appears at $T_{\rho}$. At higher doping, above the quantum critical point where antiferromagnetic order disappears (in the absence of superconductivity), both...
the upturn and the anisotropy in $\rho$ vanish.\textsuperscript{33} Note that the antiferromagnetic order also causes the Nernst signal to be enhanced in pnictide superconductors.\textsuperscript{36,37}

The overall phenomenology is seen to be remarkably similar to that of YBCO. The unidirectional order that breaks translational symmetry and reconstructs the Fermi surface at low temperature is preceded at high temperature by a regime with strong in-plane transport anisotropy, evidence of broken rotational symmetry. In Co-Ba122, it is very natural to view this regime as the nematic precursor to the smectic phase at low temperature. The analogy supports the view that the pseudogap phase in YBCO is just such a precursor to stripe order.

It is interesting to note that in Co-Ba122 the in-plane anisotropy in $\rho$ is not largest at $x = 0$, where the order is strongest ($T_N$ is highest). Indeed, the ratio $\rho_b/\rho_a$ at $T \rightarrow 0$ is larger at $x > 2\%$ than at $x = 0$.\textsuperscript{33} This could well be due to a short-circuiting effect similar to that observed in YBCO, whereby a small and isotropic Fermi pocket of high mobility dominates the conductivity. Indeed, the concentration $x \simeq 0.02$ in Co-Ba122 appears to be a Lifshitz critical point, as suggested by ARPES experiments that reveal the existence of a small hole pocket for $x < 0.02$, and not above.\textsuperscript{34} Such a pocket could short circuit the in-plane anisotropy coming from other parts of the Fermi surface.

**V. CONCLUSION**

In summary, the Nernst effect is a highly sensitive probe of electronic transformations in metals. In the cuprate superconductor YBCO, the onset of the pseudogap phase at $T^\star$ causes a 100-fold enhancement of the quasiparticle Nernst coefficient, which goes smoothly from $\nu_b/T = +0.07 \text{ nV/K}^2\text{T}$ at $T^\star$ to $\nu_b/T = -7 \text{ nV/K}^2\text{T}$ at $T \rightarrow 0$, in the normal (nonsuperconducting) state. This enhancement is strongly anisotropic in the plane, suggesting that the pseudogap phase is a state that breaks the rotational symmetry of the CuO$_2$ planes. When the Fermi-surface reconstructs at low temperature, the formation of a high-mobility electron pocket short circuits this in-plane anisotropy. The magnitude of $\nu/T$ at $T \rightarrow 0$ is in perfect agreement with the value expected from the small closed Fermi pocket detected in quantum oscillations. The negative sign proves that the signal comes from quasiparticles and not superconducting fluctuations or vortices. There is compelling evidence that the Fermi-surface reconstruction is caused by a stripe order which breaks the translational symmetry of the CuO$_2$ planes at low temperature,\textsuperscript{3} but also its rotational symmetry. The sequence of broken symmetries upon cooling, first rotational then translational, suggests a process of nematic-to-smectic stripe ordering, similar to that observed in the iron-pnictide superconductor Co-Ba122, where a phase of spin-stripe antiferromagnetic order prevails in the underdoped region of the temperature-concentration phase diagram. The analogy suggests that the enigmatic pseudogap phase of hole-doped cuprates is also a high-temperature precursor of a stripe-ordered phase, with unidirectional charge and/or spin modulations. This nematic interpretation is consistent with the in-plane anisotropy of the spin fluctuation spectrum detected by neutron scattering in underdoped YBCO.\textsuperscript{35}
